SUMMARY

We derive a stable cross-correlation type imaging condition for shot-profile migration which produces common-angle gathers with correct amplitude-versus-angle relationship or conventional stacks with better estimates for the angle-averaged reflectivity. The method is simple to implement and requires a modification of the initial wavefield in the downward propagation and decomposition into plane-waves in the midpoint-slowness domain We show that the cross-correlation true-amplitude imaging condition arises naturally from wave theory through the solution of a simple forward problem.

INTRODUCTION

Claerbouts (1971) cross-correlation imaging condition for shot-profile migration has been extensively used due to its simplicity and stability. Designed for structural imaging it is expected and well known that stack amplitudes produced with this approach do not represent a true average of the angle dependent reflectivity. Claerbout (1971) also introduced the imaging condition which gives correct stack amplitudes, but is difficult to implement due to the instability of spectral division. A wide variety of approaches to stabilize the imaging have been investigated (see f.ex. Schleicher et al. 2007 and Guitton et al. 2007) but a simple and satisfactory solution remains to be found. We derive a stable cross-correlation type imaging condition for shot-profile migration which produces common-angle gathers with correct amplitude-versus-angle relationship or conventional stacks with better estimates for the angle-averaged reflectivity. The method is simple to implement and requires a modification of the initial wavefield in the downward propagation and decomposition into plane-waves in the midpoint-slowness domain (de Bruin et al, 1990). Zhang et al. (2007) introduced a similar cross-correlation type imaging condition, but based on ray-theoretical arguments. Here we show that the cross-correlation true-amplitude imaging condition arises naturally from wave theory through the solution of a simple forward problem.

THEORY

We consider the simplified situation of a single reflecting interface at depth z with reflection coefficient R and where the wave velocity and density are constant above the reflector. In the frequency-wavenumber domain the relation between the up-going wave U and downgoing wave D, can then be expressed as

$$U(\mathbf{k}, z, \omega) = R(\mathbf{k}, z, \omega) D(\mathbf{k}, z, \omega), \qquad (1)$$

where $\mathbf{k}$ is the horizontal wavenumber with components (k_x, k_y), z is the depth and ω is the frequency. The downgoing wave at depth z is related to the downgoing wave at the surface, D_0, by the relation

$$D(\mathbf{k}, z, \omega) = \exp\left[-ik_z(\mathbf{k}, \omega)z\right] D_0(, \omega), \qquad (2)$$

where k_z is the vertical wavenumber. For a point source the downgoing wave at the surface is given by

$$D_0(\mathbf{k}, \omega) = \exp(-i\mathbf{k}q)\frac{S(\omega)}{2ik_z(\mathbf{k})}, \qquad (3)$$

where q is the horizontal position of the source and $S(\omega)$ is the source pulse. Equation 1 can be solved as

$$R(\mathbf{k}, z, \omega) = \frac{U(\mathbf{k}, z, \omega)}{D(\mathbf{k}, z, \omega)}, \qquad (4)$$

which becomes by inserting equation 2 into equation 4

$$R(\mathbf{k}, z, \omega) = U(\mathbf{k}, z, \omega)D'^*(\mathbf{k}, z, \omega). \qquad (5)$$

Here D' is a downgoing wavefield

$$D'(\mathbf{k}, z, \omega) = \exp\left[-ik_z(\mathbf{k}, \omega)z\right] D_0'(\mathbf{k}, \omega), \qquad (6)$$

with the initial wavefield D_0' at the surface equal to

$$D_0'(\mathbf{k}, \omega) = \exp(-i\mathbf{k}q)\frac{-2ik_z}{S^*(\omega)}. \qquad (7)$$

Equation 5 expresses the reflection coefficient as a product between the wavefields U and D'^* instead of a division as in equation 4. This has the advantage of avoiding numerical instabilities related with spectral division.

For a medium with vertical and lateral velocity changes, it can be shown that equation 5 must be modified to read

$$R(\mathbf{k}_r, \mathbf{k}_s, z, \omega) = U(\mathbf{k}_r, z, \omega)D'^*(\mathbf{k}_s, z, \omega), \qquad (8)$$

where $R(\mathbf{k}_r, \mathbf{k}_s, z, \omega)$ is the reflectivity matrix, $\mathbf{k}_r$ is the horizontal wavenumber of the upgoing wave and $\mathbf{k}_s$ is the horizontal wavenumber of the downgoing wave. The initial downgoing wavefield at the surface, $D_0'(\mathbf{k}_s)$, is given by equation 3, except that the source pulse $S(\omega)$ must be replaced by $S(\omega)(c_0^2/\omega^2)$ where c_0 is the velocity at the source position. In the spatial domain equation 8 becomes

$$R(\mathbf{x}_m, \mathbf{h}, z, \omega) = U(\mathbf{x}_m - \mathbf{h}, z, \omega)D'^*(\mathbf{x}_m + \mathbf{h}, z, \omega), \quad (9)$$

where we have also introduced the midpoint and offset coordinates $\mathbf{x}_m$ and $\mathbf{h}$. Finally, inverse transforming equation 9 over the offset coordinate and introducing the offset slowness we get after integration over frequencies and summation over shots

$$R(\mathbf{x}_m, \mathbf{p}_h, z) = \sum_{shots} \int_{-\infty}^{+\infty} d\omega \int_{-\infty}^{+\infty} d\mathbf{h} \exp(i\omega\mathbf{p}_h)R(\mathbf{x}_m, \mathbf{h}, z, \omega),$$

$$(10)$$

which gives the reflectivity matrix as a function of midpoint and slowness. Equation 9 is similar to Rickett and Savas (2002) offset imaging condition, except that the downgoing field is replaced by the modified downgoing field . Claerbouts (1971) classical cross-correlation shot-profile imaging condition is obtained as a special case for $\mathbf{h} = 0$ from equation 9.

NUMERICAL EXAMPLES

Figure 1 shows a simple horizontally layered model with density contrasts between the layers. The wave velocity is constant equal to 2000 m/s. A line of synthetic data consisting of 200 shots where acquired across the model using a split-spread geometry with a maximum half-offset of 5km. A single shot is shown in Figure 2(a) together with a common angle gather computed using equation 10 and then converting the slowness $\mathbf{p}_h$ into the corresponding angle using all 200 shots.

Density = 1.0 g/ccm

1 Km

Density = 1.2 g/ccm

2 Km

Density = 1.0 g/ccm

3 Km

Density = 1.2 g/ccm
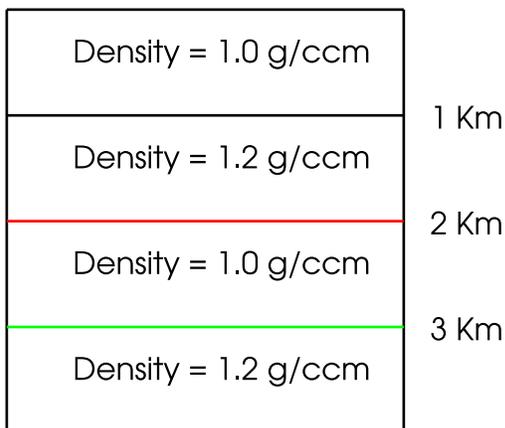

Figure 1: Horizontally layered acoustic earth model with density contrasts only.

Figure 3 shows rms amplitude picks of the angle gather shown in Figure 2(b). The rms amplitude values were computed in a 200 ms window around each of the three reflectors. A common scaling factor for all the three amplitude graphs were used, such that the relative amplitude relations between the three reflectors are preserved. We see that the correct amplitude-versus-angle behavior is recovered, since a reflector with a pure density contrast has an angle independent reflection coefficient. The imaging condition given by Rickett and Sava (2002) is designed for structural imaging and not expected to yield correct amplitude-versus-angle behavior, but it is still of interest to compare the amplitude response of this imaging condition with our condition given by equation 10. Since Rickett and Sava (2002) compute the reflectivity matrix in the midpoint-offset domain

$$R_{rs}(\mathbf{x}_m, \mathbf{h}, z, \omega) = U(\mathbf{x}_m - \mathbf{h}, z, \omega) D^*(\mathbf{x}_m + \mathbf{h}, z, \omega), \quad (11)$$

where D is now the downgoing wavefield due to a point source (see equation 2), we use this expression to generate angle gathers by using equation 10 with R replaced by R_{rs}.

The resulting gather is shown in Figure 4 , and the corresponding amplitude picks are shown in Figure 5. We see that the angle-versus-angle behavior is incorrect, particularly for large angles. Claerbouts classical cross-correlation imaging condition corresponds to stacking the gather in Figure 4 across all angles, and it is clear that the amplitudes of a stack section

(b)

Figure 2: Single shot (a) acquired over the earth model shown in figure 1 The acquisition geometry is of split-spread type with maximum half offset of 5 km. A common angle gather (b) was computed using equation 10 and 200 shots.
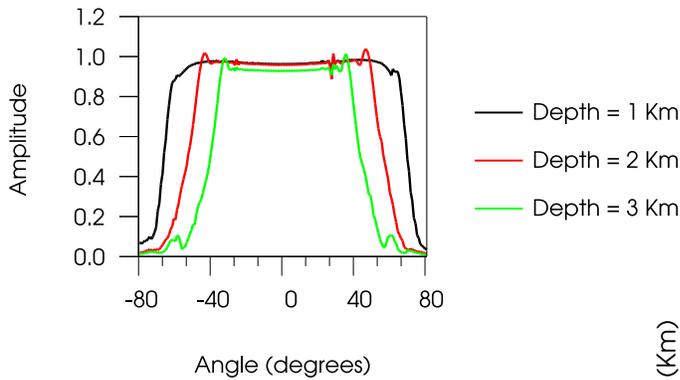

Figure 3: Rms amplitude picks of the common angle gather shown in Figure 2(b)

in this case do not represent an average of the true angle-dependent reflectivity but is instead biased. For the case of a plane reflector the large angles would contribute too much, and this would in particular tend to overestimate the reflection strength of shallow reflectors relative to deeper ones. The imaging condition given in equation (10) can also be used for cases with complex velocity models, provided that the corresponding up- and downgoing wavefields are computed correctly. To that end any one-way extrapolation scheme can be used. For cases of non-flat reflectors, although the reflectivity matrix is correctly computed, the mapping from slowness to angle is non-trivial and will also involve corrections of the amplitude. These corrections can, however, be computed separately after the migration itself.

STACK AMPLITUDES

Claerbout's imaging condition implies averaging the reflectivity matrix over horizontal wavenumbers, and hence angles. In general amplitudes of events with large angles will be overemphasized, as demonstrated in Figure 5. In very broad terms one would expect that shallow events with large angles will tend to appear with incorrect stack-amplitudes. Figure 6(a) shows a zero-offset stack computed using equation 9, while Figure 6(b) shows the same data set using Claerbout's cross-correlation imaging condition. As expected, the two sections are quite similar, except that the amplitudes of shallow events in Figure 6(b) seem to be larger relative to deeper events in the same section than is the case for Figure 6(a). Figure 7 shows stack traces from Figure 6(a) (upper trace) and Figure 6(b) (lower trace). We see that amplitudes on the stack trace obtained using the new imaging condition given by equation 9 seem to be better balanced than the stack trace obtained with Claerbout's cross-correlation imaging condition.

CONCLUSION

Claerbouts (1971) cross-correlation imaging condition can be modified to a true-amplitude cross-correlation type imaging condition by changing the source of the downgoing wavefield. Essentially this modification deconvolves the spatial response of the seismic point source and restores the amplitudes in the final image.
