## ABSTRACT

CO<sub>2</sub> saturations are estimated at Sleipner using a two-step imaging workflow. The workflow combines seismic tomography (full-waveform inversion) and rock physics inversion and is applied to a two-dimensional seismic line located near the injection point at Sleipner. We use baseline data (1994 vintage, before CO<sub>2</sub> injection) and monitor data that was acquired after 12 years of CO<sub>2</sub> injection (2008 vintage). P-wave velocity models are generated using the Full waveform inversion technology and then, we invert selected rock physics parameters using an rock physics inversion methodology. Full waveform inversion provides high-resolution P-wave velocity models both for baseline and monitor data. The physical relations between rock physics properties and acoustic wave velocities in the Utsira unconsolidated sandstone (reservoir formation) are defined using a dynamic rock physics model based on well-known Biot–Gassmann theories. For data prior to injection, rock frame properties (porosity, bulk and shear dry moduli) are estimated using rock physics inversion that allows deriving physically consistent properties with related uncertainty. We show that the uncertainty related to limited input data (only P-wave velocity) is not an issue because the mean values of parameters are correct. These rock frame properties are then used as *a priori* constraint in the monitor case. For monitor data, the Full waveform inversion results show nicely resolved thin layers of CO<sub>2</sub>–brine saturated sandstones under intra-reservoir shale layers. The CO<sub>2</sub> saturation estimation is carried out by plugging an effective fluid phase in the rock physics model. Calculating the effective fluid bulk modulus of the brine–CO<sub>2</sub> mixture (using Brie equation in our study) is shown to be the key factor to link P-wave velocity to CO<sub>2</sub> saturation. The inversion tests are done with several values of Brie/patchiness exponent and show that the CO<sub>2</sub> saturation estimates are varying between 0.30 and 0.90 depending on the rock physics model and the location in the reservoir. The uncertainty in CO<sub>2</sub> saturation estimation is usually lower than 0.20. When the patchiness exponent is considered as unknown, the inversion is less constrained and we end up with values of exponent varying between 5 and 20 and up to 33 in specific reservoir areas. These estimations tend to show that the CO<sub>2</sub>–brine mixing is between uniform and patchy mixing and variable throughout the reservoir.

**Key words:** CO<sub>2</sub> storage monitoring, Full Waveform Inversion, Rock physics inversion, Quantitative imaging, Saturation estimation.

## INTRODUCTION

The global warming is gaining lots of attention in the last decade with the increasing energy demand and fossil energy

consumption. Excessive CO<sub>2</sub> emissions that have a substantial contribution to the global warming (Metz *et al.* 2005) require the implementation of immediate mitigation measures. The CO<sub>2</sub> Capture and Storage (CCS) technology is hence proposed as a mean to reduce the CO<sub>2</sub> emission into the atmosphere.

\*E-mail: bastien.dupuy@sintef.no

Large CO<sub>2</sub> storage capacity has already been proven in deep saline aquifers (Halland *et al.* 2011; Böhm *et al.* 2015). The Sleipner CO<sub>2</sub> storage site is the first commercial-scale offshore storage operation and the longest in operation in the world. Geophysical monitoring (including seismic and non-seismic techniques) is used to monitor the subsurface changes related to the CO<sub>2</sub> plume migration, in order to verify conformance and early detection of potential leakage (containment monitoring).

The seismic monitoring programme at Sleipner includes a three-dimensional baseline survey prior to CO<sub>2</sub> injection and several monitor surveys every 2–3 years (Arts *et al.* 2008; Furre, Kiær and Eiken 2015; Furre *et al.* 2017). Previous studies based on time-lapse analysis help to reveal the details of the CO<sub>2</sub> plume development (Eiken *et al.* 2000; Arts *et al.* 2002; Arts *et al.* 2004). Structural mapping and frequency decomposition have been used to estimate the upper most layer thickness (Williams and Chadwick 2012; White 2013). Arts *et al.* (2002) give quantitative estimates of CO<sub>2</sub> mass using amplitude information. More recently, Furre *et al.* (2015) perform a detailed analysis of the thin CO<sub>2</sub> layers, with respect to time shift development and amplitude changes.

The proper understanding of saturation development in Utsira sandstone has been widely studied by several authors. Ghaderi and Landrø (2009) use seismic modelling of thin layer responses and propose a simultaneous inversion of velocity and layer thicknesses of partially saturated layers with CO<sub>2</sub>. Post-stack impedance analysis (Ghosh, Sen and Vedanti 2015) and time-lapse Amplitude Versus Offset (AVO) analysis (Chadwick *et al.* 2010) have been applied to estimate CO<sub>2</sub> saturations. Bergmann and Chadwick (2015) propose a method using time-shift analysis to estimate the influence of fluid mixing law both with synthetic and real data. As an alternative, quantitative maps of velocity properties derived at Sleipner using full waveform inversion (FWI) have been used as input to estimate saturation distributions. Queiber and Singh (2013) and Romdhane and Querendez (2014) apply FWI in order to derive highly resolved P-wave velocity models. Queiber and Singh (2013) use simple rock physics relations (Gassmann (1951) model combined with Brie's law (Brie *et al.* 1995)) to describe the CO<sub>2</sub> and brine mixture from the P-wave velocity. Dupuy, Garambois and Virieux (2016) propose a two-step workflow with dynamic rock physics models to tackle the existing limitation in frequency sensitivity and obtain reliable reservoir properties from high-resolution velocity models. Sensitivity studies have highlighted that extra input data in the inversion process, such as shear wave velocity and P-wave quality

factors are important for the estimation of rock frame moduli and can be helpful to better constrain in the estimation of CO<sub>2</sub> saturation (Böhm *et al.* 2015; Dupuy *et al.* 2016; Dupuy *et al.* 2017). At Sleipner, Dupuy *et al.* (2017) show however that the estimation of CO<sub>2</sub> saturations from P-wave velocity models derived from FWI is still possible.

In this work, FWI is combined with the rock physics inversion (RPI) method to invert for selected poroelastic properties (rock frame moduli, porosity, CO<sub>2</sub> saturation and Brie patchiness exponent) and to derive high-resolution maps of CO<sub>2</sub> saturation with uncertainty. Data from 1994 and 2008 vintages are used. The rock frame properties are recovered using baseline data and used as *a priori* parameters to estimate CO<sub>2</sub> saturation distribution with the monitor dataset. We invert the CO<sub>2</sub> saturation and other properties for the monitor case and we constrain the inversion using *a priori* geological information (fluid properties, grain properties, permeability and cementation factor) and *a priori* information derived from the baseline results (bulk modulus, shear modulus and porosity). We also analyse how the Brie exponent, describing the fluids distribution (from uniform to patchy mixing), is affecting the results.

This paper is divided into four sections. While the first part gives the methodology workflow, the second section provides a short description of the geological context at Sleipner justifying the choice of some *a priori* parameters. Tests presented in section 3 provides expected sensitivities for estimation of rock frame properties and CO<sub>2</sub> saturation and distribution. The case study at Sleipner, for both baseline and monitor data are described in section 4.

## METHODOLOGY

We use a two-step workflow combining full waveform inversion (FWI) and rock physics inversion (RPI) methods. From FWI, we generate a P-wave velocity model that is used as input of the RPI step.

FWI is performed in the frequency-space domain (Pratt, Shin and Hick 1998). The two-dimensional acoustic wave equation is solved using finite differences with the mixed grid approach (Hustedt, Operto and Virieux 2004). The inverse problem is solved using a pre-conditioned gradient algorithm. The gradient method in its standard form provides a relationship between the perturbation model and the data residuals. An approximation of the Hessian operator with only the diagonal elements is used to save computation cost. Basic data pre-processing steps (including quality control of the data, offset selection, muting and coordinate transformation)

are performed before running the inversion (Romdhane and Querendez 2014). We derive an initial P-wave velocity model using root mean square velocity in time converted into interval velocity in depth. The misfit function and the gradient of the misfit at iteration  $n$  can be expressed:

$$\xi(\mathbf{m}) = \frac{1}{2} \|\mathbf{d}_{\text{mod}} - \mathbf{d}_{\text{obs}}\|^2, \quad (1)$$

$$\frac{\partial \xi(\mathbf{m}_n)}{\partial \mathbf{m}} = \Re \{ \mathbf{J}^T \delta \mathbf{d}^* \},$$

where  $\frac{\partial \xi(\mathbf{m}_n)}{\partial \mathbf{m}}$  is the gradient of the misfit at iteration  $n$ .  $\mathbf{d}_{\text{mod}}$  and  $\mathbf{d}_{\text{obs}}$  are the modelled and observed data, respectively.  $\Re$  is the real part of a complex number.  $\mathbf{J}$  denotes the Jacobian matrix, thus  $\mathbf{J}^T$  is the transpose of the Jacobian matrix.  $\delta \mathbf{d}^*$  denotes the conjugate of the data residuals. The perturbation model is given by:

$$\delta \mathbf{m}_n = \mathbf{m}_{n+1} - \mathbf{m}_n. \quad (2)$$

The gradient method can be formulated as the link between the perturbation model and data residuals, and is given as:

$$\delta \mathbf{m}_n = -\alpha_n \frac{\partial \xi(\mathbf{m}_n)}{\partial \mathbf{m}}, \quad (3)$$

where  $\alpha_n$  is the step length at iteration  $n$ . Proper scaling and regularization can be applied to ensure the computational stability. The approximate Hessian  $\mathbf{H}_a$  can be written:

$$\mathbf{H}_a = \Re \{ \mathbf{J}^T \mathbf{J}^* \}. \quad (4)$$

If we only consider the diagonal term of the approximate Hessian, the model update at iteration  $n$  becomes:

$$\delta \mathbf{m}_n = -\alpha_n (\text{diag} \mathbf{H}_{a_n} + \lambda \mathbf{I})^{-1} \frac{\partial \xi(\mathbf{m}_n)}{\partial \mathbf{m}}, \quad (5)$$

where  $\lambda$  denotes a damping parameter used to ensure computational stability.

The second step consists in solving the inverse problem linking seismic properties and rock physics properties. The link between rock physics parameters and seismic attributes constitutes the forward problem, usually called the rock physics model. The forward problem can be described in a generic manner by Biot–Gassmann theory (Gassmann 1951; Biot 1956a) as long as rock frame properties are somehow defined or estimated.

The Biot–Gassmann equations are valid under several assumptions. The Gassmann equations are valid within a low frequency limit and do not account for the chemical interaction between the grains and the fluid phases. The Biot theory is limited to homogeneous and isotropic media, which consists of only one type of grain. To be more realistic, Pride (2005)

extended the Biot–Gassmann equations and included a generalized dynamic permeability (Johnson, Koplik and Dashen 1987). The extended Biot–Gassmann theory can be applied to a multi-composite material saturated with a multi-fluid mixture using averaging techniques. In addition, this approach is valid within a wide frequency range. More details on the assumptions and theory for this rock physics model are given in Pride (2005). The extensive Biot–Gassmann equations allow us to calculate the viscoelastic attributes for an effective fluid phase even if only P-wave velocity is used.

Biot (1956b) demonstrates that there are three types of waves propagating in a fluid saturated porous medium. These are compressional wave (P-wave), shear wave (S-wave) and an additional slow compressional wave (Biot wave or slow P-wave). The slowness of P-wave is formulated by Pride (2005) as:

$$S_p^2(\omega) = \frac{\gamma(\omega)}{2} - \frac{1}{2} \sqrt{\gamma^2(\omega) - \frac{4(\rho \tilde{\rho}(\omega) - \rho_f^2)}{HM - C^2}}. \quad (6)$$

Thus, we can deduce the effective P-wave velocity as:

$$V_p(\omega) = \frac{1}{\text{Re}(S_p(\omega))}. \quad (7)$$

In equation (6),  $\rho$  and  $\rho_f$  and  $\tilde{\rho}(\omega)$  are the bulk density, the effective fluid density and the flow resistance term, respectively. Note that  $\omega$  is the complex pulsation and is involved in frequency-dependent terms such as  $\tilde{\rho}(\omega)$  and  $\gamma(\omega)$ . The undrained bulk modulus  $K_U$ , the Biot modulus  $C$ , the shear modulus  $G$  and the fluid storage coefficient  $M$  are the four mechanical moduli. The additional terms  $\gamma(\omega)$  and  $H$  are defined by:

$$\gamma(\omega) = \frac{\rho M + \tilde{\rho}(\omega) H - 2\rho_f C}{HM - C^2},$$

$$H = K_U + \frac{4}{3} G. \quad (8)$$

The four mechanical moduli are related to the homogenized porous solid.  $K_U$ ,  $C$  and  $M$  are formulated as:

$$K_U = \frac{\phi K_d + (1 - (1 + \phi) K_d / K_s) K_f}{\phi(1 + \Delta)},$$

$$C = \frac{(1 - K_d / K_s) K_f}{\phi(1 + \Delta)},$$

$$M = \frac{K_f}{\phi(1 + \Delta)}, \quad (9)$$

where the term  $\Delta$  is given by:

$$\Delta = \frac{1 - \phi}{\phi} \frac{K_f}{K_s} \left( 1 - \frac{K_d}{(1 - \phi) K_s} \right), \quad (10)$$

where porosity  $\phi$  is defined as the ratio between void and total volume in the solid matrix.  $K_d$ ,  $G_d$ ,  $K_s$  and  $K_f$  are respectively the frame bulk modulus, the frame shear modulus, the grains bulk modulus and the effective fluid bulk modulus. The undrained shear modulus  $G$  is assumed to be equal to dry shear modulus  $G_d$ .

We consider that the solid material for both shale and sand layers consists of a mix of clay and quartz grains. We compute the grains bulk moduli  $K_s$  by averaging the bounds (Hashin and Shtrikman 1963). The grain density  $\rho_s$  is computed using an arithmetic average:

$$\rho = (1 - \phi)\rho_s + \phi\rho_f. \quad (11)$$

The extended Biot–Gassmann formulation given by Pride (2005) is valid over a wide range of frequency because it involves Johnson *et al.* (1987) model which gives a frequency-dependent dynamic permeability  $k(\omega)$ . It allows for correcting the seismic permeability and differentiates the viscous and inertial predominant effects at low and high frequency domain (Dupuy *et al.* 2016). The dynamic permeability  $k(\omega)$  is expressed by Johnson *et al.* (1987):

$$k(\omega) = \frac{k_0}{\sqrt{1 - \frac{1}{2}i\frac{\omega}{\omega_c} - i\frac{\omega}{\omega_c}}}, \quad (12)$$

where  $\omega$  is the angular frequency.  $\omega_c$  is the characteristic angular frequency that characterizes the maximum attenuation peak.  $k_0$  is the hydraulic permeability and  $i$  is the complex number. The characteristic frequency  $\omega_c$  can be formulated with the cementation factor  $m$ , the effective fluid viscosity  $\eta$

and the effective fluid density  $\rho_f$  (Adler, Jacquin and Thovert 1992) such as:

$$\omega_c = \frac{\eta}{\rho_f k_0 \phi^{-m}}. \quad (13)$$

Then, we can define frequency-dependent flow resistance term  $\tilde{\rho}(\omega)$  that is involved in the slowness equation (6) and is defined by:

$$\tilde{\rho}(\omega) = \frac{i\eta}{\omega k(\omega)}. \quad (14)$$

For the monitor step, it is assumed that the fluid phase in the pore space can be treated as a single-phase mixture of brine and CO<sub>2</sub>, with effective properties computed using Brie mixing law (Brie *et al.* 1995) for fluid bulk modulus, Teja and Rice equation (Teja and Rice 1981) for effective viscosity and arithmetic average (Voigt 1928) for fluid density. The sensitivity tests provided in Dupuy *et al.* (2016) show that the fluid bulk modulus is the main factor affecting the P-wave velocity change. The Brie equation involves an empirical exponent  $e$ :

$$K_f = (K_{CO_2} - K_W)S_W^e + K_{CO_2}, \quad (15)$$

where  $S_W$  denotes the brine saturation,  $K_{CO_2}$  and  $K_W$  denote the CO<sub>2</sub> and brine bulk moduli, respectively. The exponent  $e$  can vary between 1 and 40 (Brie *et al.* 1995), which corresponds to various mixture trends (Fig. 1). For instance, the lower bound ( $e = 40$ ) stands for the so-called uniform mixing (the two fluids are mixed at the finest scale), while the upper bound ( $e = 1$ ) stands for the so-called patchy mixing. It is worth noting that the patchy mixing is related to empirical observations and its definition is variable depending on the authors. The exponent  $e$  is proposed to be equal to 3 (Brie *et al.*

Figure 1 P-wave velocity variation with brine saturation for various patchiness exponents.

1995) and 5 (Carcione and Picotti 2006) to match the case related to gas and brine mixture. The Brie exponent  $e$  is sometimes called patchiness exponent (Papageorgiou, Amalokwu and Chapman 2016). The set of rock physics model equations (6)–(14) constitute the forward model that allows us to compute visco-elastic attributes (mainly P-wave velocity) from rock physics properties (solid and fluid phases and rock frame properties).

To solve the RPI problem, we use a semi-global optimization method (Neighbourhood Algorithm (NA) (Sambridge 1999)) to minimize the discrepancy between observed data and calculated data obtained by forward modelling. The method searches for the global minimum over the whole model space in a partially random way and the search process is guided by each iteration towards areas with a lower misfit. The scalar misfit function  $C(\mathbf{m})$  between the observed data  $\mathbf{d}_{\text{obs}}$  and the estimated data  $\mathbf{g}(\mathbf{m})$  from the forward modelling can be given as an L2 norm:

$$C(\mathbf{m}) = \left[ (\mathbf{d}_{\text{obs}} - \mathbf{g}(\mathbf{m}))^T (\mathbf{d}_{\text{obs}} - \mathbf{g}(\mathbf{m})) \right]. \quad (16)$$

$\mathbf{m}$  is the model vector describing the model space. The NA algorithm has only two control parameters: the number of new models at each iteration and the resampling size of Voronoï cells. The misfit of the previous iteration decides the new sampling of Voronoï cell for the next iteration. Sambridge (1999) and Dupuy *et al.* (2016) provide more details on the NA algorithm and the RPI, respectively.

The RPI process give estimates of selected parameters with the related uncertainty. The sensitivity study by Dupuy *et al.* (2017) shows that the estimation of CO<sub>2</sub> saturation from P-wave velocity input only is not well constrained when the CO<sub>2</sub> saturation is high (it is directly related to the shape of the P-wave velocity versus saturation curve, see Fig. 1). Examples of the misfit function shapes for the estimation of frame parameters and saturation are given in sensitivity tests. By assuming a Gaussian distribution of estimated models, we can estimate the mean value and associated standard deviations to assess the uncertainty.

## GEOLOGICAL BACKGROUND

Since 1996, about 0.9 million tons of CO<sub>2</sub> is annually injected into the Utsira formation at Sleipner at a depth of 1012 m below the sea level through a deviated well (Arts *et al.* 2008). The thickness of the Utsira sandstone is about 300 m and is surrounded by the Nordland shale on the top and the Hordaland shale on the bottom. The caprock is assumed to be a good quality seal with a low probability of leakage (Chadwick *et al.*

2004). The Utsira formation consists of late Miocene to early Pliocene dominantly sandy unit and some shaly intra-reservoir horizons (Chadwick *et al.* 2000). It is a highly porous, unconsolidated, permeable sandstone that shows good reservoir properties for high injection rate through only one single well (Michael *et al.* 2010). The intra-reservoir shale layers are very thin and can be less than 1 m thick (Zweigel 2000).

To constrain our rock physics inversion (RPI), we need to determine a set of realistic *a priori* rock physics properties. These parameters are defined based on the existing geological studies on Sleipner field. Grain moduli  $K_s$  of the Utsira sandstone and the Nordland shale are calculated by the Hashin–Shtrikman bounds method (Hashin and Shtrikman 1963; Mavko, Mukerji and Dvorkin 2009). Grain density  $\rho_s$  for the Utsira sandstone and the Nordland shale are computed using volume weighted averages. The cementation parameter  $m$  (Pride 2005) is assumed to be equal to 1 for the unconsolidated sandstone and mudstone. As discussed in sensitivity tests by Dupuy *et al.* (2016), the cementation factor has a negligible influence on P-wave velocity. The permeability for the Utsira formation is high and ranges from  $1 \times 10^{-12} \text{ m}^2$  to  $3 \times 10^{-12} \text{ m}^2$  (Boait *et al.* 2012). We use an average permeability of  $2 \times 10^{-12} \text{ m}^2$  for Utsira formation. The permeability of Nordland shale is defined from laboratory data and assumed to be equal to  $1.48 \times 10^{-17} \text{ m}^2$ . The grains and rock frame properties of Utsira sandstone and Nordland shale are given in Table 1.

We consider a CO<sub>2</sub> and brine mixture after CO<sub>2</sub> injection and a fully brine saturated medium before CO<sub>2</sub> injection for the saturating fluids properties. The bulk modulus of brine is equal to 2.3 GPa at reservoir conditions (Boait *et al.* 2012), and the density of brine is assumed to be equal to 1030 kg/m<sup>3</sup> (Mavko *et al.* 2009) at reservoir temperature and pressure. Most of the CO<sub>2</sub> is stored in a supercritical state (Arts *et al.* 2008) and we use a relatively high density of 700 kg/m<sup>3</sup> for the CO<sub>2</sub> phase (Lindeberg 2013). Since the initial pore pressure of 8 MPa is considered (Furre and Eiken 2014) and the reservoir temperature is ranging between 27°C (top Utsira formation) and 37°C (near injection point), the range of  $K_{\text{CO}_2}$  is estimated

Table 1 Utsira sandstone and Nordland shale properties

Lithology	Grain Properties		Rock Frame Properties	
	$K_s$ GPa	$\rho_s$ kg/m <sup>3</sup>	$m$	$k_o$ m <sup>2</sup>
Utsira Sandstone	39.29	2663.5	1	$2 \times 10^{-12}$
Nordland Shale	22.6	2390	1	$1.48 \times 10^{-17}$

Table 2 Brine and CO<sub>2</sub> properties

Fluid phase	Fluid Properties		
	$\eta$ Pa.s	$\rho_f$ kg/m <sup>3</sup>	$K_f$ GPa
Brine	$6.9 \times 10^{-4}$	1030	2.3
CO <sub>2</sub>	$6 \times 10^{-5}$	700	0.075

to be equal to 0.02 GPa to 0.075 GPa (Ghaderi and Landrø 2009). We use a value of 0.075 GPa for bulk modulus of CO<sub>2</sub> (Lindeberg 2013) regarding *in situ* pressure and temperature conditions. The viscosity of CO<sub>2</sub> is discussed in many papers and depends on the temperature and pressure (Singh et al. 2010; Gasda et al. 2012). However, the effective viscosity influence on seismic velocity is minor at low frequency (Dupuy and Stovas 2016). We use  $6 \times 10^{-5}$  Pa.s for the CO<sub>2</sub> viscosity. The fluids properties used in the case study are summarized in Table 2. As CO<sub>2</sub> is under a supercritical state and reservoir pressure and temperature conditions are known, we have chosen to fix the CO<sub>2</sub> properties and not estimate them. Otherwise, sensitivity tests have been carried out to estimate CO<sub>2</sub> properties in addition to saturation (Dupuy et al. 2017). The tests show that the CO<sub>2</sub> saturation estimates are only slightly affected if CO<sub>2</sub> properties are unknown.

## SENSITIVITY TESTS

Sensitivity tests for baseline parameters, i.e. porosity and rock frame moduli before CO<sub>2</sub> injection are carried out. The forward model is based on the extended Biot–Gassmann theory with fully brine saturated Utsira sandstone, and is described in the methodology part. The grain and frame properties for Utsira sandstone and brine properties are given in Tables 1 and 2.

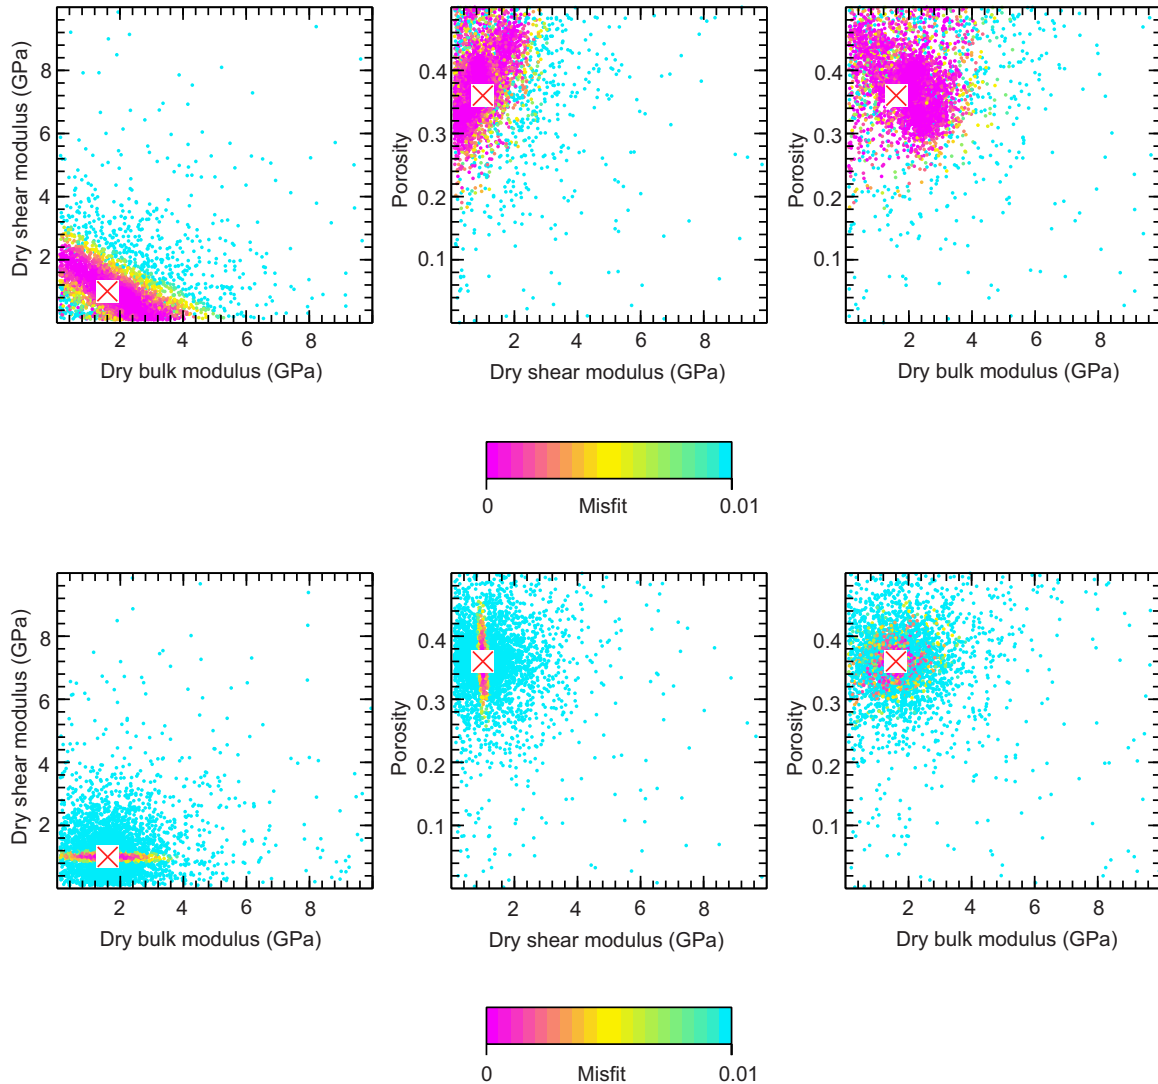

Figure 2 (bottom panel) shows a point test where we estimate frame bulk modulus, frame shear modulus and porosity using a different combination of input data (P-wave, S-wave velocity and density). Examining the size and the shape of the low misfit area in these sensitivity plots allows assessing the uncertainty of each parameter estimate and how well these estimates are constrained depending on which input data are used. The computation of S-wave velocity as well as extensive sensitivity tests are described in details in Dupuy et al. (2016). In Fig. 2, the low misfit area is wider when only P-wave velocity is used than when P-wave, S-wave velocities and density are input data. The dry shear modulus is a lot better constrained when using  $V_p$ ,  $V_s$  and  $\rho$  inputs, but porosity and dry bulk

modulus have similar uncertainty. It is also worth noting that mean values of all low misfit models (pink models) are quite close to the true value, even when only P-wave velocity is used. This is a promising conclusion for the real data application where acoustic full waveform inversion is used to derive P-wave velocity maps.

Similar sensitivity tests are given for CO<sub>2</sub> saturation and Brie exponent estimates in Fig. 3. We observe that the CO<sub>2</sub> saturation is correctly estimated when the saturation is low, while it is more difficult to get an accurate estimate when CO<sub>2</sub> saturation is high. This effect is directly related to the shape of the  $V_p$ - $S_{CO_2}$  curve (Fig. 1) where we have a quick drop of  $V_p$  as soon as little CO<sub>2</sub> is present in the porous medium (fizz-gas effect). However, for Brie exponent larger than 5 (fluid mixture is becoming more and more homogeneous), a change of CO<sub>2</sub> saturation is not affecting P-wave velocity when this saturation is greater than 30–50%. The inversion is consequently more difficult to constrain for high CO<sub>2</sub> saturations and the related uncertainty is larger. It is worth noting that this sensitivity test is carried out using  $V_p$  input only. Supplementary tests show that using additional input help to mitigate this issue of non-linearity (Dupuy et al. 2017). This first test is assuming that the fluid mixing law is known (Brie exponent equal to 5). If this patchiness exponent is inverted together with CO<sub>2</sub> saturation (bottom panel of Fig. 3), we observe a trade-off between these two parameters that is expected as only P-wave velocity is used as input. The uncertainty of the saturation estimates is consequently larger.

## SLEIPNER TEST CASE

The two-step workflow is carried out for data before (1994 vintage, baseline) and after CO<sub>2</sub> injection (2008 vintage, monitor). For both vintages, seismic data from inline 1836 (north-south orientation, close to injection point) is extracted. The applied processing workflow aims at improving the signal to noise ratio without affecting the amplitudes of the data. It includes the removal of the  $t^2$  divergence compensation, data muting before the first arrivals and the selection of data with an offset higher than 420 m. The available data include offsets up to 1800 m. For the initial velocity model, we assume a horizontal sea bottom and use a stacking velocity model converted to interval velocity in depth and smoothed. The model is 7 km long and has a depth of 1.35 km. It is defined on a regular 3 m squared grid to ensure sufficient accuracy when high frequencies are considered. To mitigate the non-linearity of full waveform inversion, we perform the inversion from low to high frequencies using frequency components up to

**Figure 2** Estimation of dry shear modulus, dry bulk modulus and porosity from P- wave velocity (top panels) and from P-wave and S-wave velocities and density (bottom panel). The red cross indicates the true model. The colour of each dot represents the absolute misfit value for each computed model (between 0 and 0.01).

33 Hz to derive a highly resolved P-wave velocity model. A target region around the Utsira sandstone is then used as input to perform rock physics inversion.

### FWI results

Figure 4(a,b) shows the P-wave velocity maps derived by full waveform inversion (FWI) for both baseline and monitor cases, respectively. Selected interpreted horizons (corresponding to the seabed, the top Pliocene, the intra Pliocene, the top of Utsira sand wedge, the top of Utsira and the base of Utsira) are also plotted for reference. The top of Utsira

sand wedge is an eastward thickening package, which is separated from the main sand part by a shale layer (Zweigel *et al.* 2004). As observed in Romdhane and Querendez (2014) using a different inline, the models derived from FWI show a clear improvement in term of resolution. Figure 4(b) shows clear indications about the lateral extent and geometry of the CO<sub>2</sub> plume. Figure 4(c) shows the corresponding time-migrated section converted to depth using a simple time to depth relationship based on well data situated at around 800 m distance from the two-dimensional line used. The push-down of the reflection beneath the CO<sub>2</sub> plume is clearly visible.

**Figure 3** Estimation of brine saturation  $S_W$  (top panels) and estimation of brine saturation and patchiness exponent (bottom panels) from P-wave velocity (Figures from Dupuy et al. 2017). The blue cross indicates the model with the lowest misfit and the red cross indicates the true model. Below each panel are indicated the true value for CO<sub>2</sub> saturation and Brine exponent. The colour of each dot represents the absolute misfit value for each computed model (between 0 and 0.01; all models with misfit higher than 0.01 are clipped).

Close-up of the target region at the depth of Utsira reservoir where the CO<sub>2</sub> is expected to accumulate are shown in Fig. 4(d,e) with interpreted horizons corresponding to the top of Utsira sand wedge, the top of Utsira and to the base of Utsira from top to bottom. For the baseline case, two thick low-velocity layers can be observed. These layers are probably showing high porosity unconsolidated sandstones where the CO<sub>2</sub> is expected to migrate after injection. For the monitor case, we observe thin low velocity layers that can be associated with the accumulation of CO<sub>2</sub>. The velocity pushdown effect at the base of the Utsira can also be observed. The better resolution of the shale-sand interlayers is probably related to the higher contrast between the slow-velocity CO<sub>2</sub> plume and

the surrounded high-velocity brine-saturated reservoir, shale overburden and interbedded layers. It is worth noting that the velocities of the overburden layers (just above Utsira reservoir) are slightly lower in the monitor case, while no effect related to CO<sub>2</sub> anomaly should be observed. In addition, velocity differences observed below the reservoir are not meaningful of any physical change because CO<sub>2</sub> migration is driven by buoyancy effect. These uncertainties in velocity can be partly due to some smearing effects (Queiber and Singh 2013; Romdhane, Querendez and Ravaut 2014) that can lead to overestimation of velocities in the CO<sub>2</sub> plume (i.e. underestimation of velocity change) observed in Utsira sandstone, and to the limited available offset range (maximum of 1800 m).

**Figure 4** (a) P-wave velocity model of baseline vintage (1994) derived by FWI, (b) P-wave velocity model of monitor vintage (2008) derived by FWI. (c) Time migrated section converted to depth of monitor vintage (2008). (d, e) Close-ups around the reservoir where CO<sub>2</sub> is injected for (d) baseline and (e) monitor models. The injection point is located at 1012 m deep. The FWI has been carried out with limited offset (1800 m) with frequencies inverted up to 33 Hz. The black lines (and blue lines in (c)) correspond to selected interpreted horizons. For the full sections (a, b, c), the black lines are indicating the seabed, the top Pliocene, the intra Pliocene, the top of Utsira sand wedge, the top of Utsira and the base of Utsira from top to bottom. For the close-up sections (d, e), the black lines are indicating the top of Utsira sand wedge, the top of Utsira and the base of Utsira from top to bottom. The base of the Utsira taking into account the pushdown effect is added to (c).

### Baseline dataset: Estimation of rock frame properties

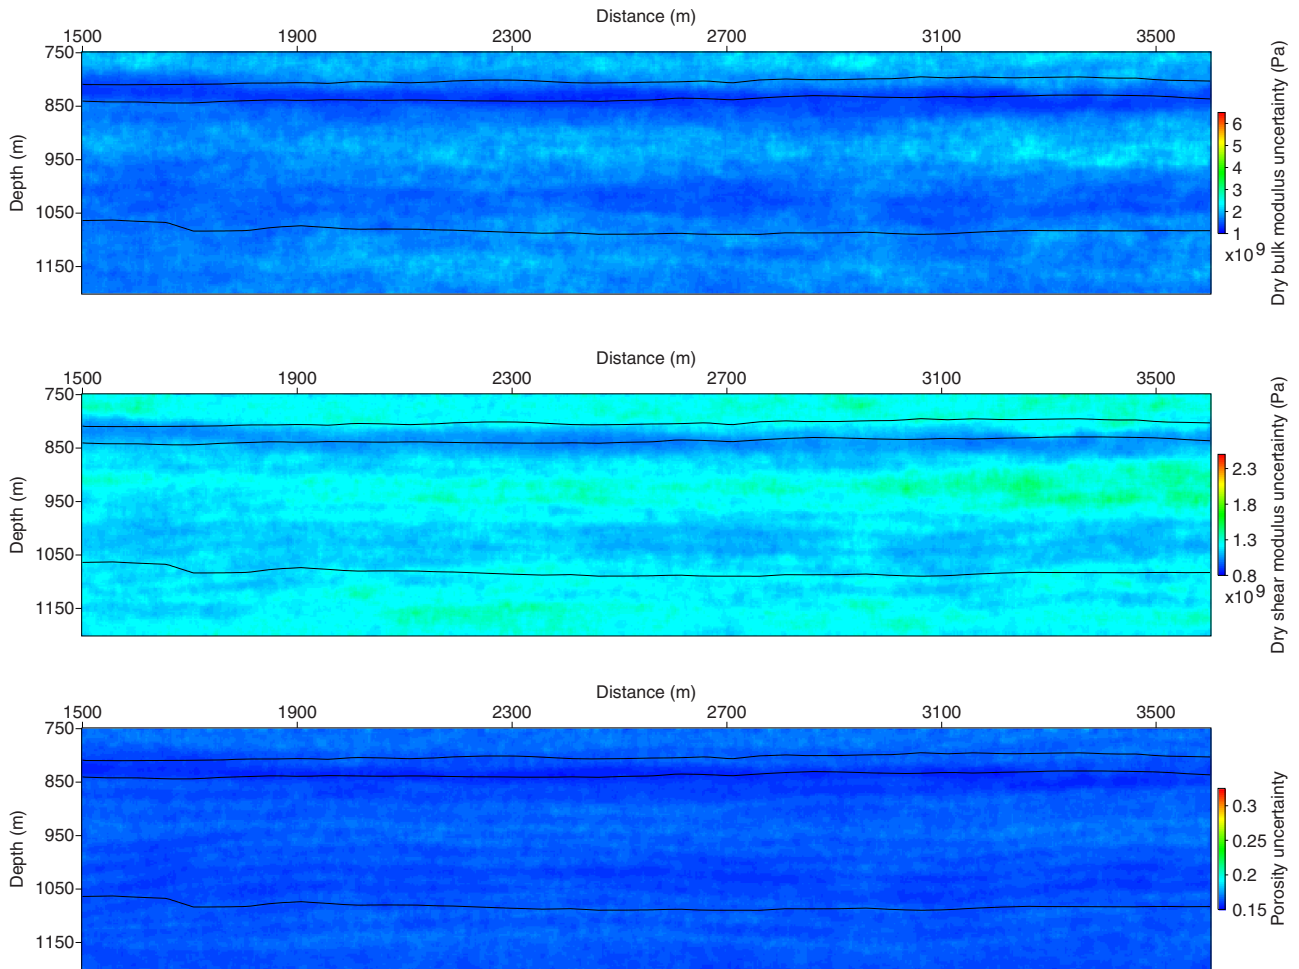

We apply the rock physics inversion (RPI) on baseline data considering that the porous medium is saturated with brine. Prior geological information is helpful to constrain the estimation of rock frame properties (Dupuy *et al.* 2016). The RPI is applied to the full waveform inversion derived P-wave velocity model to estimate rock frame moduli ( $K_d$ ,  $G_d$ ) and porosity  $\phi$  for the reservoir where the CO<sub>2</sub> plume is expected to accumulate. The inversion ranges are given as:  $0.1 \text{ GPa} < K_d < 10 \text{ GPa}$ ,  $0.01 \text{ GPa} < G_d < 10 \text{ GPa}$ ,  $0 < \phi < 0.45$ . The inversion frequency is 30 Hz.

The estimated bulk frame modulus, shear frame modulus and porosity and associated uncertainties are given in Figs 5

and 6. The bulk and shear frame moduli within the two low-velocity sand layers vary from 1 to 3 GPa with  $\pm 1$  to 1.5 GPa uncertainty and from 1 to 1.5 GPa with  $\pm 0.9$  to 1.2 GPa uncertainties, respectively. The surrounding layers (interpreted as being thin shale interbedded layers and the overburden layers) show higher values for both moduli (3 to 6 GPa with  $\pm 1.5$  to 2.5 GPa for the bulk modulus and 2 to 2.5 GPa with  $\pm 1.15$  to 1.5 GPa for the shear modulus). The porosity varies from 0.30 to 0.35 with  $\pm 0.05$  to 0.075 uncertainty in the sands, while it shows lower values in the surrounding layers (0.20 to 0.25 with  $\pm 0.075$  to 0.10 uncertainty). It is worth noting that we can observe the imprint of the *a priori* parameters (grain density, grain bulk moduli and permeability) on the porosity map (Fig. 5). It is also noticed that the high porosity layers are slightly shifted compared to the interpreted layers. This can be

**Figure 5** From top to bottom: frame bulk modulus  $K_d$ , frame shear modulus  $G_d$  and porosity  $\phi$ . The black lines are figuring the interpreted horizons, i.e. the top of Utsira sand wedge, the top of Utsira and the base of Utsira from top to bottom.

**Figure 6** From top to bottom: inversion uncertainty of frame bulk modulus  $K_d$ , frame shear modulus  $G_d$  and porosity  $\phi$ . The black lines are figuring the interpreted horizons, i.e. the top of Utsira sand wedge, the top of Utsira and the base of Utsira from top to bottom.

caused by a partially erroneous time to depth conversion of interpreted horizons and related to the smearing effect observed in full waveform inversion (FWI) results. However, knowing that expected resolution of FWI is around half a wavelength that corresponds to approximately 30 m for a frequency of 33 Hz and a velocity of 2000 m/s, this depth mismatch of 10 m maximum is in the range of uncertainty. That is why we chose to not do any stretch matching of these horizons.

#### Monitor dataset: Estimation of CO<sub>2</sub> saturation and patchiness exponent

After the estimation of rock frame properties, we focus on the 2008 vintage dataset for the target region. Figure 7 shows the maps of CO<sub>2</sub> saturation using Brie rock physics model

with two exponent values ( $e = 1$  and  $e = 5$ ), and when  $e$  is inverted together with saturation. Figure 8 shows the associated uncertainties of CO<sub>2</sub> saturation for the three cases. Figure 9 shows the estimation of patchiness exponent and its associated uncertainty for the third case (joint inversion of CO<sub>2</sub> saturation and Brie exponent). The estimation of CO<sub>2</sub> saturation using  $e = 1$  (so-called patchy mixing) shows clear CO<sub>2</sub>-brine-saturated regions, mainly around 880–970 m deep with saturations reaching  $0.90 \pm 0.15$ – $0.17$  uncertainty. The estimations of CO<sub>2</sub> saturation within deeper sandstone layers are lower than 0.50 with  $\pm 0.12$  to 0.17 uncertainty.

The estimation of CO<sub>2</sub> saturation using exponent  $e = 5$  also shows one high CO<sub>2</sub>-brine-saturated region (870–970 m deep). CO<sub>2</sub> saturation in this layer varies from 0.30 to 0.70 with  $\pm 0.15$  to 0.17 uncertainty. Especially, the highest uncertainty tends to be associated with the highest CO<sub>2</sub>

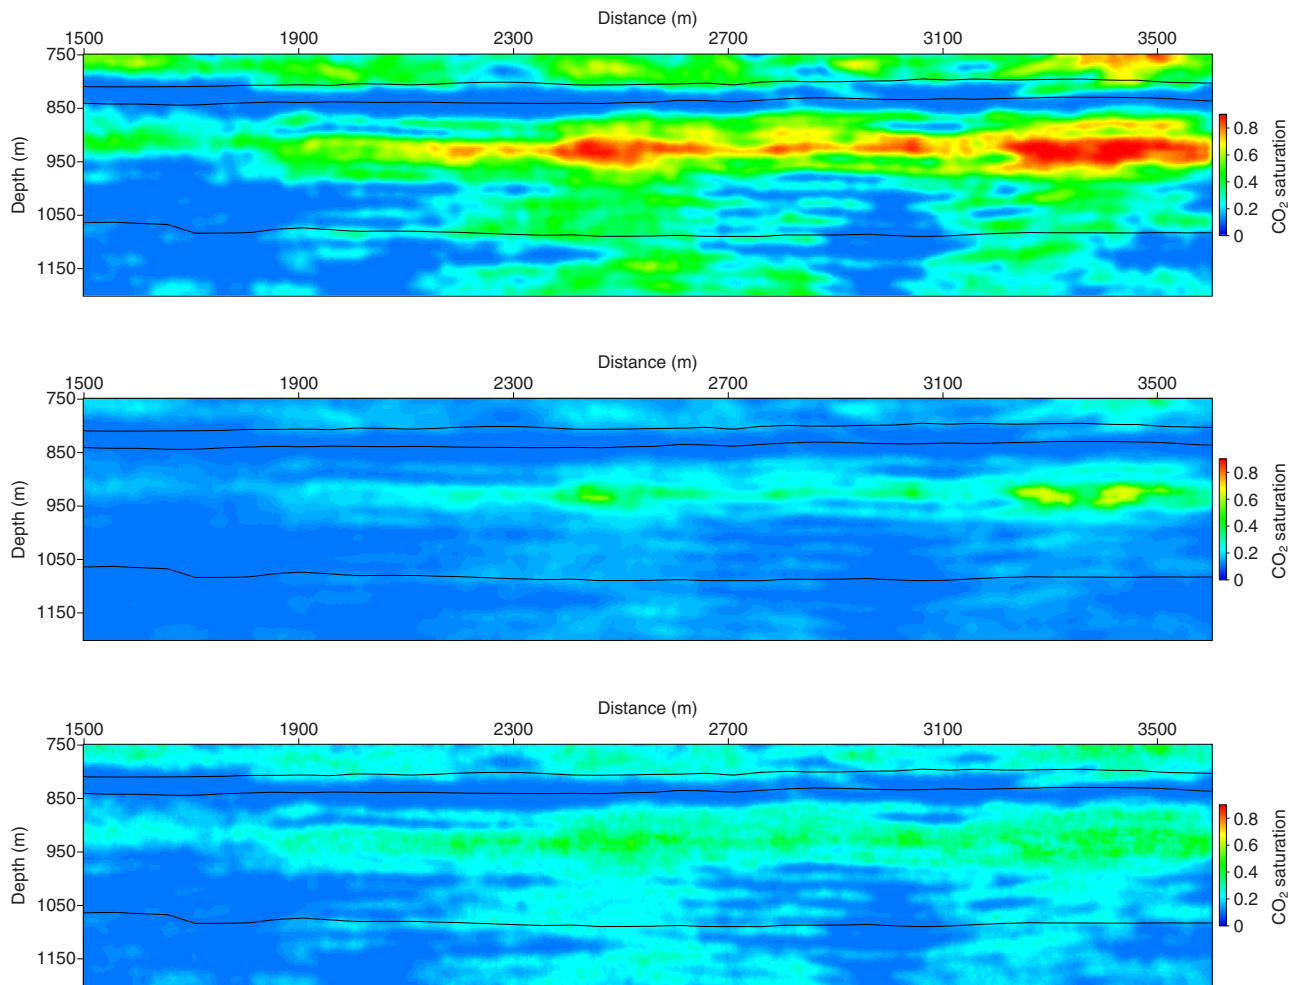

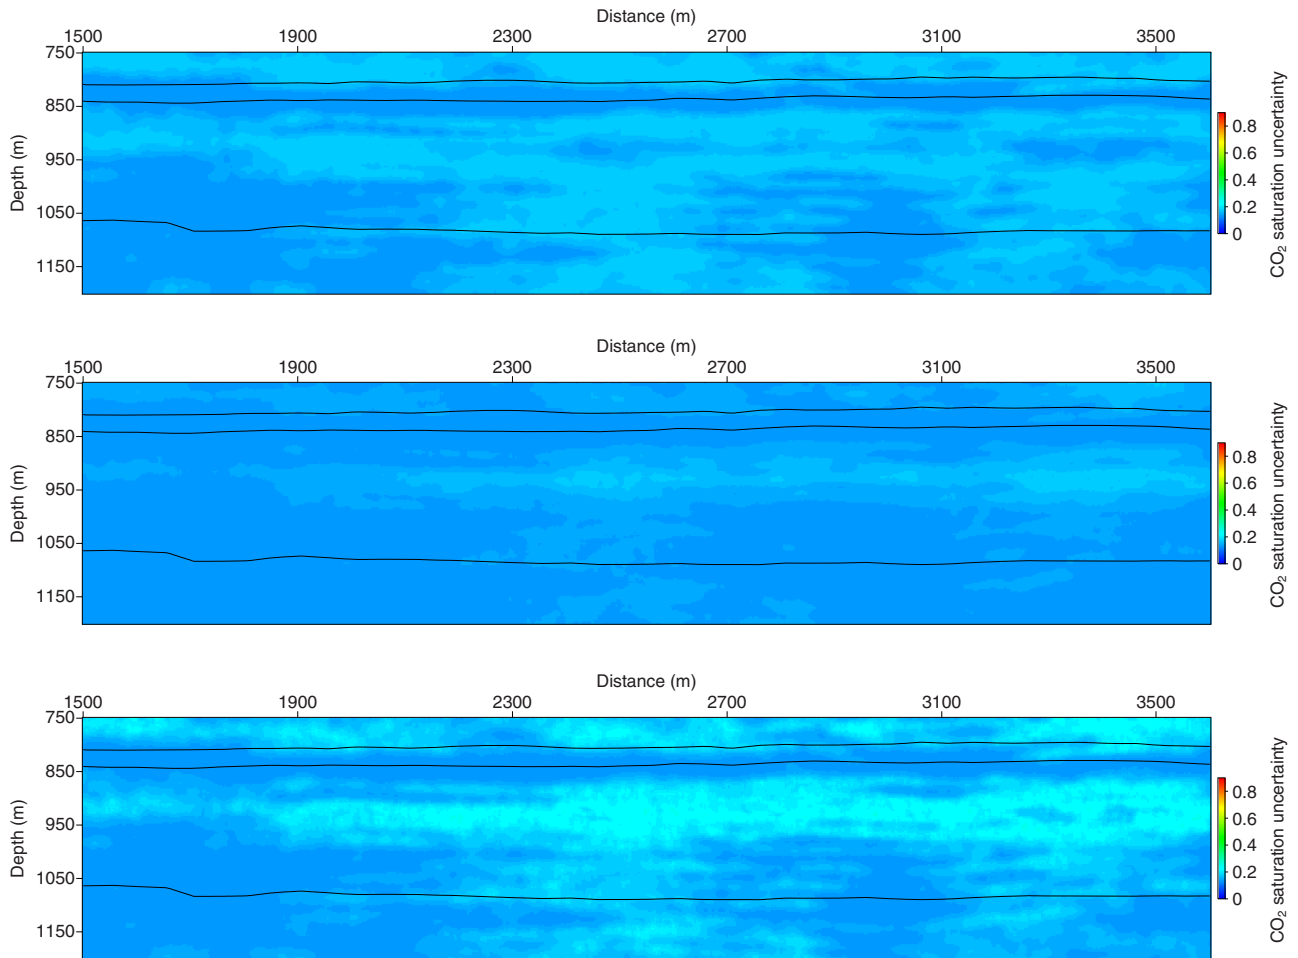

Figure 7 From top to bottom: CO<sub>2</sub> saturation estimated by RPI using patchiness exponent  $e = 1$ ,  $e = 5$  and exponent inverted (given in Fig. 9).

saturated regions. For example, at 910–940 m deep, the CO<sub>2</sub> saturation is going up to 0.70 with  $\pm 0.17$  uncertainty. We can also see this distinct high CO<sub>2</sub> saturated region at the depth of approximately 900 m when we invert for the Brie (or patchiness) exponent and CO<sub>2</sub> saturation simultaneously. In this case, the CO<sub>2</sub> saturation is reaching 0.50 in this main layer with an uncertainty around 0.22–0.25. The estimations of CO<sub>2</sub> saturations within the deeper sandstone layers vary in the range of 0.20–0.30 with  $\pm 0.13$  to 0.17 uncertainty. It is worth noting that uncertainties related to CO<sub>2</sub> saturation estimates are higher in this third case, up to 0.25 instead of 0.17 in the two first cases. The patchiness exponent  $e$  within these CO<sub>2</sub>–brine-saturated layers is ranging from 4 to 33 with an uncertainty around 5–11. Again, the higher uncertainty in CO<sub>2</sub> saturation tends to be associated with the high CO<sub>2</sub> saturated regions, while lower uncertainty and higher value in the estimation of the patchiness exponent tend to be

associated with the high CO<sub>2</sub> saturated regions. For example, the estimations of patchiness exponent vary in the range of 31–36 with  $\pm 5$  uncertainty at depth of 910–940 m where the CO<sub>2</sub> saturation is reaching 0.50. High CO<sub>2</sub> saturation and uniform mixing tend to happen at the same locations.

It is worth noting that there are large CO<sub>2</sub> saturations above the top Utsira in Fig. 7, especially for the case where Brie exponent is equal to 1 (top panel). This feature in overburden should not be interpreted as leaking CO<sub>2</sub>. It is linked to the low velocity patch (green-blue colours) observed in Fig. 4(e). It is important to note that this high saturation value is only visible for the patchy saturation case ( $e = 1$ ) and that the results of CO<sub>2</sub> saturation estimates are affected by uncertainties both related to the first (FWI) and second inversion steps (RPI). The full waveform inversion (FWI) step is dependent on data quality that is different for the baseline (1994 vintage) and monitor (2008 vintage) datasets, making any

**Figure 8** From top to bottom: inversion uncertainty of  $\text{CO}_2$  saturation estimated by RPI using patchiness exponent  $e = 1$ ,  $e = 5$  and exponent inverted (given in Fig. 9).

quantification of 4D changes difficult. For this reason, we opted for a parallel time-lapse FWI strategy. The baseline data is used in our case to derive constraints on rock frame properties in the reservoir. Smearing effect in FWI results can also be a source of 'ghost' changes above and below the reservoir as noticed in Fig. 4. In addition, the overburden shales have low porosity (<20%) and complex mineralogy, so additional caution must be considered when looking at  $\text{CO}_2$  saturations in the overburden because of greater uncertainties in *a priori* constraints. Finally, Biot–Gassmann theory combined with the effective fluid phase rock physics model have been shown to be relevant for fluid substitution in brine– $\text{CO}_2$  saturated sands but its applicability for shales is less straightforward (Queiber and Singh 2013; Bergmann and Chadwick 2015; Dupuy *et al.* 2017; Falcon-Suarez *et al.* 2018). High  $\text{CO}_2$  saturation estimates in the overburden are

consequently not reliable and no conclusion of any leaking  $\text{CO}_2$  should be derived from this result.

Figure 10 shows the one-dimensional profiles of  $\text{CO}_2$  saturation and patchiness exponent for the different test cases. The profile is extracted at an offset of 3240 m going through the high  $\text{CO}_2$  saturation zone. The main  $\text{CO}_2$ –brine saturated layers appear between 900 and 950 m deep with  $\text{CO}_2$  saturation ranging from 0.60 to 0.90. It is interesting that both patchy mixing ( $e = 1$  or  $e = 5$  depending on authors) and uniform mixing ( $e = 40$ ) models show  $\text{CO}_2$  saturations reaching 0.90. The  $\text{CO}_2$  saturation increases when the patchiness exponent decreases, which is directly related to the shape of the velocity versus saturation curves (Fig. 1). It is worth noting that the results for exponent equal to 1 are enveloping the other results showing more high-resolution variations. When we invert patchiness exponent and  $\text{CO}_2$  saturation at the same time,

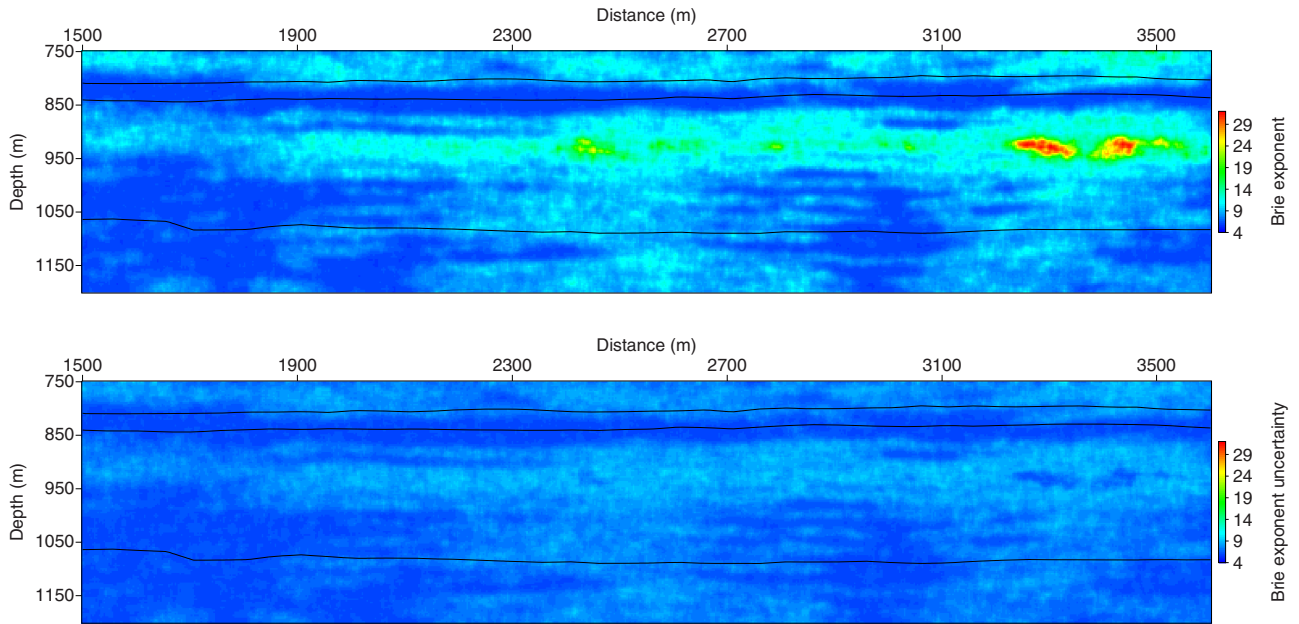

Figure 9 From top to bottom: estimation of patchiness exponent and related uncertainty. The patchiness has been inverted together with CO<sub>2</sub> saturation (given in Fig. 7, bottom panel).

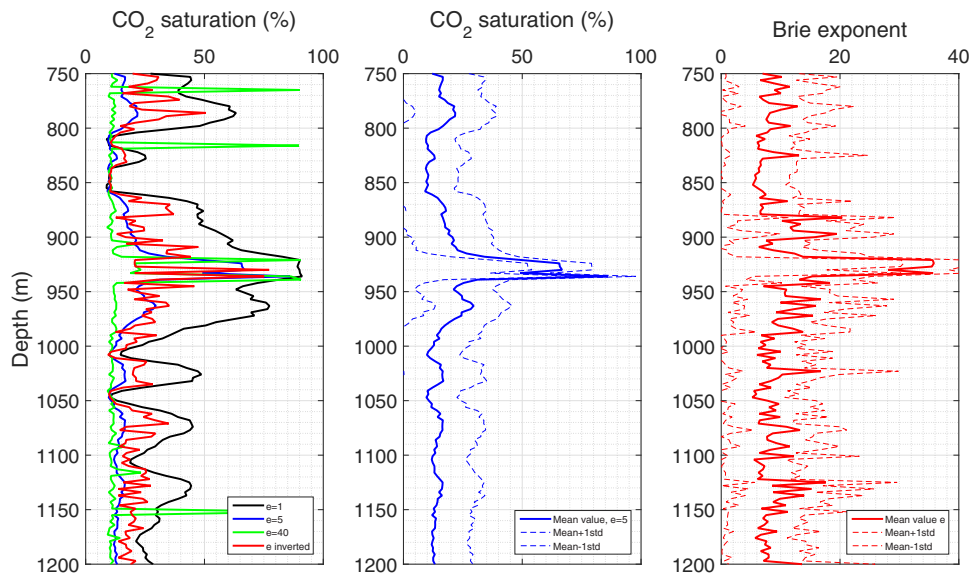

Figure 10 From left to right: 1D profiles of CO<sub>2</sub> saturation estimation using different patchiness exponents, 1D profiles of CO<sub>2</sub> saturation estimation and related uncertainty for  $e = 5$  and 1D profiles of patchiness exponent and related uncertainty. The 1D profiles are extracted for an offset equal to 3240 m. The dotted lines correspond to the mean values and the dashed lines stand for the mean value  $\pm$  one standard deviation.

we observe more oscillations due to the under-determined inversion system. The uncertainty for the estimation of CO<sub>2</sub> saturation varies in the range of  $\pm 0.12$ – $0.17$ , when we are using a known Brie exponent. When we invert the CO<sub>2</sub> saturation and the patchiness exponent together, the associated uncertainty of CO<sub>2</sub> saturation goes up to  $\pm 0.25$ .

## DISCUSSION

In our study, velocity models from both the baseline and monitor datasets and these velocity models are used as input to infer rock physics properties. The inversion of the monitor dataset provides clear indications about the geometry and

lateral extent of the CO<sub>2</sub> plume with the lowest P-wave velocities being in the uppermost layers. We opted for a parallel time-lapse strategy where models from velocity analysis are used as initial models for the inversion. Alternative strategies (Asnaashari *et al.* 2015), including the use of a sequential time-lapse inversion and the introduction of *a priori* information (for example about the overburden), can contribute to the improvement of the derived models.

The values of CO<sub>2</sub> saturation obtained for inline 1836 are higher than those obtained in Dupuy *et al.* (2017). The inline data used in our study is located very close to the injection point, while the one-dimensional section shown in Dupuy *et al.* (2017) is located approximately 500 m away from the injection point. For comparison, Queiber and Singh (2013) get values up to 0.90 using 2006 vintage, while Golding *et al.* (2011) suggest that saturation is probably higher than 0.30. Recent work by Ghosh *et al.* (2015) gives estimations between 0.20 and 0.80 depending on the mixture type (patchiness exponent). In previous tests using the same methodology shown by Dupuy *et al.* (2017), rock frame properties are derived from well-log data acquired at the injection well. The effect of *a priori* properties (i.e., rock frame, grains and fluid parameters) on CO<sub>2</sub> saturation estimates can strongly affect the results, and these *a priori* parameters should be handled with care. Estimating them from baseline data can be a better solution. It is anyway worth keeping in mind that uncertainty related to baseline estimates (bulk and shear moduli as well as porosity) is not negligible and is a key factor in the CO<sub>2</sub> saturation quantification. Even if our sensitivity tests show that the mean values of these baseline properties estimated from P-wave velocity only are close to the true value, uncertainty is not negligible and other sensitivity tests show that the CO<sub>2</sub> saturation can be changed by 0.10 to 0.20 if the baseline properties are different.

Regarding the mixture distribution, Sen, Ghosh and Vedanti (2016) use a capillary pressure equilibrium theory and show that the CO<sub>2</sub> distribution at Sleipner is more uniform for high CO<sub>2</sub> saturation and more patchy for low CO<sub>2</sub> saturation. We found similar trends in our results. For example, the patchiness exponent is higher for the highly CO<sub>2</sub> saturated layers, which is indicating a more uniform mixing while the patchiness exponent is smaller for the less CO<sub>2</sub> saturated layers. Ghosh *et al.* (2015) also found that the CO<sub>2</sub> phase is not fully patchy or uniformly saturated in the reservoir. Zhang, Lu and Zhu (2014) and Chadwick *et al.* (2010) propose an approach using history-matching simulations and 4D seismic data. They get higher values of CO<sub>2</sub> saturation with some values up to 0.98. In our study, the highly saturated layers show

saturations varying between 0.60 and 0.90 with an uncertainty of 0.12–0.20. Lumley *et al.* (2008) suggest that it is difficult to quantify the CO<sub>2</sub> saturation when it is larger than 0.30. In our study, we also observe that the estimated uncertainty is higher for higher CO<sub>2</sub> saturation (Figs 1 and 3). Relevant uncertainty assessment and quantification still need to be carried out. Proper uncertainty propagation from seismic imaging (using the method suggested in Eliasson and Romdhane (2017) for example) to rock physics inversion can be taken into account using a fully Bayesian formulation. More constraints to the inversion process could be added to mitigate the trade-off between saturation and patchiness exponent (standing for the rock physics model itself). For example, using additional inputs from seismic inversion (attenuation, shear wave velocity, AVO attributes) or from other geophysical techniques (gravity, CSEM) can lead to reduce the non-uniqueness of the inversion (Gao, Abubakar and Habashy 2012; Liang, Abubakar and Habashy 2016; Subagio *et al.* 2018).

## CONCLUSIONS

We derive a quantitative spatial distribution of CO<sub>2</sub> saturation through the combination of full waveform inversion and rock physics inversion. The two-step workflow is applied to a selected inline from both baseline and monitor surveys at Sleipner. We first estimate rock frame properties based on baseline data that are then used as an input to the monitor vintage study. We find that CO<sub>2</sub> saturations can reach 0.60–0.90 ± 0.12–0.25 near the injection point when the patchiness exponent is assumed to be known. The uncertainty of the CO<sub>2</sub> saturation estimation is relatively low for most cases but tends to increase for higher CO<sub>2</sub> saturations. We show the possibility to estimate the CO<sub>2</sub>–brine mixture law by estimating the patchiness exponent and CO<sub>2</sub> saturation simultaneously. The patchiness exponent is globally varying from 5 to 33, which indicates a distribution of CO<sub>2</sub> and brine between fully patchy ( $e = 1$ ) and fully uniform ( $e = 40$ ) mixings. Uniform mixing prevails when CO<sub>2</sub> saturation is very high.

## ACKNOWLEDGEMENTS

This publication has been produced with support from the NCCS Centre, performed under the Norwegian research program Centres for Environment-friendly Energy Research (FME). The authors acknowledge the following partners for their contributions: Aker Solutions, ANSALDO Energia, CoorsTek Membrane Sciences, Gassco, KROHNE, Larvik Shipping, Norcem, Norwegian Oil and Gas, Quad

Geometrics, Shell, Equinor, TOTAL and the Research Council of Norway (257579/E20). We thank also the uniCQue KPN project (233716/E20). We also thank Malcolm Sambridge for providing NA software and Equinor for sharing Sleipner dataset.
